Nurses and physicians: A longitudinal analysis of mobility between jobs and labor supply

By

Leif Andreassen<sup>1</sup>, Maria Laura Di Tommaso<sup>2</sup> and Steinar Strøm<sup>3</sup>

Abstract

We estimate a dynamic discrete choice model of Registered Nurses' labor supply. A distinguished feature of our model is that the random terms in the utility functions are correlated over time and jobs (habit or job persistence). Past options and not only the past optimal choices matter for the current choices. Given observed incentives and institutional constraints on offered hours, we find that nurses are mobile when they are young (less mobility than among physicians), but there is also a weak tendency of higher mobility again when they are approaching retirement age. Wage increases have a modest impact on labor supply. The overall elasticity for nurses is close to zero. These low elasticities shadow for stronger responses, shifting labor away from part time jobs in the public and private sector towards full time jobs in the private sector. A change in taxation away from the progressive tax system towards a flat tax of 28% gives Registered Nurses a very modest incentive to shift their job to private hospitals. For physicians the impact is stronger.

JEL classifications: J22, I10, C35

Keywords: Nurses' labor supply, multi-sector, panel data.

#### 1. Introduction

The main motivation for the paper is that Norway's population is ageing and the old-age dependency ratio, i.e. the ratio of the population aged 65+ to the population aged 20-64 is estimated to nearly double: from 32.7% in 2011 to 62.2% in 2050 (OECD, 2013). This is in line with the average rise for the OECD area as a whole, although the increase in Norway is less dramatic than projected in most EU countries. In the EU21 countries, the ratio is projected to increase from 37.1% in 2011 to 76.1% in 2050.

This phenomenon implies that in the coming decades there will be many elderly people requiring care in hospitals and long term care (OECD 2005). There will be a growing demand for nurses and medical doctors. This increase in demand can be covered with more nurses and medical doctors educated at Norwegian universities or migrating from abroad. The latter might be a difficult option, since most other OECD countries have the same need for people working in the health sector (OECD 2013).

In this paper, we focus on another option. We study how nurses respond to incentives to work longer hours and we compare them with medical doctors. Almost 50% of Norwegian nurses work part time and their working hours are among the lowest in the European Union (see OECD 2005). There might thus be room for increasing labor supply of nurses. Specifically, we wish to understand to what degree wages and taxes affect the labor supply of nurses. We do this by estimating a longitudinal discrete choice model on panel data for Registered Nurses. Andreassen et al. (2013) estimate a longitudinal discrete choice model on panel data for physicians. The contribution of the present paper is to estimate a similar model for nurses and to compare the results for nurses with the results for physicians published in Andreassen et al. (2013). Comparing these two groups is of great interest, because one usually thinks that they represent very different behavior in the labor market. In Norway it is generally thought that one reason for nurses to choose their profession is that it gives flexibility with respect to working hours, something that can be

important when raising a family. Doctors are, on the other hand, thought to be more motivated by prestige and money. We find that this thinking is to some extent supported by the data, with nurses having smaller wage elasticities than doctors and greater stability (habit persistence) than doctors when young.

In textbook labor supply models individuals can choose any hours of work. The choice of hours is then determined by preferences and economic incentives only. This assumption of uniformly distributed hours available in the market is at odds with how working hours are organized in hospitals and primary care. The available choices for nurses, determined by the employers and the unions, are different types of working loads. Thus, available hours is not uniformly distributed. The most suitable framework for estimating labor supply, given these institutional constraints, is a discrete choice model, first introduced in Aaberge, Dagsvik and Strøm (1995) and discussed in more detail in Dagsvik and Strøm (2006). Within this framework the deterministic preferences in choice probabilities are weighted with the densities of hours offered in the market. In a survey Creedy and Kalb (2005) coined this framework for weighted logit choice probabilities.

In the model estimated below, we allow for taste or habit persistence that may slow down mobility across jobs and working loads when wages and taxes are changed to stimulate labor supply. Habit formation and consequently habit persistence was introduced in the modelling of consumer demand by Gorman (1967) and Pollak (1970); see also Deaton (1992) for lengthy discussions of habit persistence in demand models and Dynan (2000) for a more recent empirical work related to food expenditures. So far habit formation has been introduced in consumer demand model. To our knowledge we are the first to include habit persistence attached to type of jobs in labor supply models.

The labor supply of RNs has been extensively investigated empirically during the last decades. Shields (2004) provides an excellent review of the studies. These previous models tend to be reduced form models, with a loose contact to structural decision models. Contractual arrangements are not explicitly accounted for and hence offered hours are implicitly assumed to be uniformly distributed.

By allowing habit formation in labor supply models and non-uniformly distributed offered

hours (contractual arrangements or institutional constraints), we should expect that labor supply is less elastic compared to models where these features are ignored. To test this conjecture, we have chosen to use data for the period 1997-1999. During these years the Norwegian government gave a considerable boost to the wages of nurses. Also the private sector responded by increasing wages. The annual disposable income in public hospitals and public health care increased by as much as 31-35 percent from 1997 to 1999, both for part-timers and full-timers <sup>4</sup>. The increase in the private sector was of the same magnitude. Moreover, we simulate the labor supply effects of a replacement of the current tax system with a flat tax, which reduces the marginal tax rates substantially. The aim is to check labor supply responses when economic incentives to work more are really improved.

The main conclusion is that by cutting taxes and/or increasing wages nurses move to jobs with higher working loads. However, the impact is not strong. Wage increases have the greatest effect on labor supply among nurses aged 35-50, while less progressive taxes stimulates in particular medical doctors to move to jobs with higher working loads in the private sector.

Another important result concerns the rationing or availability of jobs and thus hours offered by employers. Our model allows the estimation of the probabilities that individuals are offered different types of jobs. The results show that offered hours are more constrained for nurses than for physicians. Given observed incentives and institutional constraints, we find that nurses are more mobile when they are young (even if they are less mobile than young physicians), but there is also a weak tendency of higher mobility again when they are approaching retirement age.

On cross-sectional data from the same period as in the present paper, Di Tommaso et al. (2009) estimate a static discrete choice model of labor supply on nurses. The estimates indicate that overall labor supply is rather inelastic with an average elasticity of 0.33<sup>5</sup>. This average elasticity is similar to

<sup>&</sup>lt;sup>4</sup> See Table B.6 in Appendix B.

<sup>&</sup>lt;sup>5</sup> A 10 percent increase in the wage level for all nurses is estimated to yield a 3.3 percent increase in the unconditional expectation of hours supplied in the population of nurses. Labor supply is aggregated across individuals and job types and then the elasticities are calculated for this aggregate sum with respect to the wage rate in all job types. This aggregate elasticity is equivalent to taking the elasticity of the labor supply for every individual, and then calculating the weighted sum using the predicted choice probabilities of hours worked for each individual as weights.

the ones reported in Shields (2004), but much lower than the average elasticity (0.8) obtained on another set of Norwegian data and reported in Askildsen et al (2003). In Hanel et al (2014) the framework is similar to the one employed in Di Tommaso et al. (2009), with the exception that institutional constraints are not accounted for and the deterministic part of the utility function is quadratic. In Hanel et al. (2014), elasticities are somewhat on the high side, which is also driven by the decision of the nurse to enter or exit the profession.

Our paper shows that when estimating a dynamic model on job transitions data, accounting for habit persistence and institutional constraints, the labor supply of nurses becomes more inelastic than obtained in these previous papers, also significantly lower than in Di Tommaso et al (2009).

In the next section we give a brief but self-contained review of the model. Data is presented in Section 3. Estimates, elasticities and the result of a policy simulation are reported in the following three sections. Section 7 concludes.

#### 2. Model

The model we employ allows for habit or job persistence. This implies correlation in utilities across time. Let  $U_{jn}(t)$  be the utility of nurse n when working in job type j at time t. The utility function is assumed to be random because there are job attributes that affect preferences that we do not observe. Let  $v_{jn}(t)$  be the systematic (deterministic) part of the utility function and let  $\varepsilon_{jn}(t)$  be the random term, assumed to be independent and identical extreme value distributed. The random term accounts for the job attributes that are not observed by the econometrician. Notice that this implies that the random terms vary across job types (and individuals).

Following Dagsvik (2002) we assume that

(1) 
$$U_{jn}(t) = \max_{j} \left[ U_{jn}(t-1) - \rho, v_{jn}(t) + \varepsilon_{jn}(t) \right]$$

The expected value of  $U_{in}(t)$  is given by

(2) 
$$E\left[U_{jn}(t)\right] = \ln\left[\sum_{r=t_0}^{t} exp(v_{jn}(r) - (t-r)\rho)\right]$$

or

(3) 
$$\exp\left\{E\left[U_{jn}(t)\right]\right\} = \sum_{r=t_0}^{t} \left[\exp v_{jn}(r) - (t-r)\rho\right]$$

To calculate correlation across utilities it is convenient to calculate correlation of a monotone transformation of the utilities:

(4) 
$$corr\left\{exp\left[-U_{jn}(s)\right], exp\left[-U_{jn}(t)\right]\right\} = \frac{exp\left\{E\left[U_{jn}(s)\right]\right\}}{exp\left\{E\left[U_{jn}(t)\right]\right\}}e^{-(t-s)\rho}; for s \le t$$

We observe that if covariates are constant over time the correlation from t to t-I is approximately equal to  $e^{-\rho}$ . The coefficient  $\rho$  is a preference discount factor. If  $\rho = 0$  there is a complete strong taste or habit persistence and utilities are perfectly correlated across time. If  $\rho = \infty$  there is no taste persistence at all and  $U_{jn}(t) = v_{jn}(t) + \varepsilon_{jn}(t)$ . The inclusion of taste or habit persistence is a behavioral assumption and it implies that individuals' past options (and not only past optimal choices) matter for current choices. This implies that the current choice depends on all the utility functions associated with each alternative in the past, not only the optimal one. If  $\rho = \infty$ , the model degenerates to a standard multinomial logit model that can be estimated on panel data, see Train (2003).

From the model we can derive transition probabilities, which will be estimated on panel data. We will assume that nurse n will choose the state that maximizes utility, given his or her

choice set. Nurses can choose between 10 states, which vary with respect to type of institution (hospitals versus primary care), sector (public versus private), hours offered by the institutions in the health care sector (part time versus full time), and also not working at all (zero hours). Part time is defined as a number of hours of work less than 30. We will assume that the choice set is related to availability of jobs, characterized by offered hours. Thus, in our model the nurses are not free to choose any hours they like to work. We will assume that

(5a) 
$$g_{jnt}(h_{jnt}) = exp(d_{1j}z_{jnt}); z_{jnt} = 1 \text{ if } h_{jnt} \le 30; = 0 \text{ otherwise, (part-time)}$$

(5b) 
$$g_{jnt}(h_{jnt}) = exp(d_{2j}z_{jnt}); z_{jnt} = 1 \text{ if } h_{jnt} \ge 30; = 0 \text{ otherwise, (full-time)}$$

Note that the g(.) function captures the rationing of full time jobs and  $d_{kj}$  are parameters to be estimated for each sector j and working loads k. The g(.) functions capture the availability of full time and part time hours in the different jobs. For physicians there are only a rationing of full time jobs, while for nurses there is a rationing of part time as well as full time jobs.

Let  $Q_{ijnt}$  denote the probability that doctor or nurse n moves from state i in period t-l to state j in period t, and  $Q_{iint}$  denotes the probability that doctor or nurse n stays in state i also in period t.

With the assumed probability distribution for  $\varepsilon_{int}$ , we get (Dagsvik (2002):

$$(6) Q_{ijnt} = \frac{V_{jnt}}{\sum_{r=t_0}^{t} \left\{ \left[ exp(-(t-r)\rho) \right] \sum_{k=0}^{9} V_{knr} \right\}}; Q_{iint} = 1 - \sum_{\substack{j=0\\j \neq i}}^{9} Q_{ijnt}; \forall i, j = 0, 1, ., 9$$

where 
$$V_{jnt} = exp(v_{jnt})g_{jnt}(h_{jnt})$$

The different sectors that the nurse can choose are:

$$0 = \text{not working}^6$$

7

<sup>&</sup>lt;sup>6</sup> Implying that hours of work are zeros.

1 = working part time in a hospital in the private sector;

2 = working full time in a hospital in the private sector;

3 = working part time in primary care in the private sector;

4 = working full time in primary care in the private sector;

5 = working part time in a hospital in the public sector;

6 = working full time in a hospital in the public sector;

7 = working part time in primary care in the public sector;

8 = working full time in primary care in the public sector;

9= working in other sectors<sup>7</sup>.

## 2.1 The deterministic part of the utility function

We will assume that the systematic or deterministic part of the utility function is given by:

(7) 
$$\log v_{jnt} = (A + \sum_{s=1}^{4} a_s X_{snt}) \frac{(C_{jnt} 10^{-5})^{\lambda} - 1}{\lambda} + (B + \sum_{s=5}^{7} b_s X_{snt}) \frac{(L_{jnt})^{\gamma} - 1}{\gamma}$$

Here  $C_{int}$  is disposable annual income, and it is given by

(8) 
$$C_{jnt} = f_t(w_{jnt} 48h_{jnt} + SI_{nt}) + I_{nt},$$

The hourly wage rate is  $w_{jnt}$ ,  $48 h_{jnt}$  denotes weekly hours of work times number of working weeks per year (48),  $SI_{nt}$  is the wage income from secondary jobs and  $I_{nt}$  is non-labor income, including the after-tax income of a spouse, child benefits and other benefits. The functional form of  $f_t(.)$  depends on the characteristics of the tax function,  $T_t(.)$ , which is a step-wise linear

<sup>7</sup> The classification of sectors is based on the standard used by Statistics Norway, which is based on the statistical Classification of Economic Activities (NACE) used in the European Community. The sector "Other sectors" consists of all types of jobs that do not fall in under either hospital or health care services. It thereby includes nurses doing a wide variety of work outside the traditional health care sectors, such as administrative work in government and in the private sector or working in non-health sectors.

tax function at time t, see tables A.1-A.3 in Appendix A.

Annual leisure is denoted  $L_{jnt}$ . We assume 12 hours a day for rest and sleep. Therefore, annual leisure in this definition is equal to the total number of hours in a year (8760) minus sleeping time in a year minus hours of work. Leisure includes therefore hours in the week-ends and in vacation time:

(9) 
$$L_{jnt} = \frac{8760 - 12x365 - 48h_{jnt}}{8760}$$

Moreover  $X_{Int}$  is age and  $X_{2nt}$  is age squared. We account for the possibility that there is an impact on hours supplied when spouses are working in jobs where shift work is very common like in the health sector. We have thus included a dummy variable  $X_{3nt}$  which equals 1 if the nurse is married to a person in the health sector, and equal 0 otherwise. Other observed covariates that are included to account for observed heterogeneity are the dummy variables  $X_{4nt}$  that equals 1 if more than one job, and equal to 0 otherwise;  $X_{5nt}$  equals 1 if number of children  $\{>6,<11\}$  and finally  $X_{7nt}$  equals 1 if female, and equal to 0 otherwise.

To account for the possibility that habit persistence may increase with age (a lower preference discount parameter) we let the preference discount parameter  $\rho_{nt}$  depend on the age and age squared of the nurse:

(10) 
$$\rho_{nt} = \rho_0 + \rho_1 X_{1nt} + \rho_2 X_{2nt}$$

The wage equation is estimated separately. Selection is accounted for. An important contribution is that we allow for correlation of wages across the various jobs. Once the wage equation is estimated it is included in disable income, which is part of the utility function. The remaining parameters of the model is estimated through *simulated* maximum likelihood. The simulation is due to the fact that we have to integrate out the unobserved random terms of the wage equation. Details about the estimation procedure can be found in Andreassen et al (2013)

In Dagsvik and Jia (2015) it is shown that this type of model is non-parametrically identified.

#### 3. Data

The data used in this study are the result of merging register data from Statistics Norway with data on physicians and nurses collected by The Norwegian Association of Local and Regional Authorities (from the PAI<sup>8</sup> register). The register data from Statistics Norway consists of demographic, educational, income and labor market data. The income data is taken from tax returns, while the labor market data consist of employee data merged with data on employers. Tax functions are given in Appendix A.

The resulting panel data set covers *all* employed registered nurses in Norway in the period 1997 – 1999. Appendix B shows the data for nurses and compare them with the data for physicians as reported in Andreassen et al. (2013). We only use observations of married individuals who did not change their marital status during the observation period. Table B.1 in Appendix B shows the sample selection. The final sample has 28,578 married nurses.

We have coded the data so that we ended up with 10 different sectors of work described above. Table B.2 gives the distribution of physicians and nurses across sectors. Most nurses work in hospitals and primary care. Among working nurses, 59 percent work part-time in 1999, while only 31 percent of working physicians work part time.

Our data only included hours worked per year, so weekly hours are calculated by dividing hours worked in a year by 48 (weeks in a year minus vacation). Table B.3 shows the number of hours worked in the different sectors. Working hours for full time jobs are longer in the private sector compared to in the public sector, while working hours for part time jobs are longer in the public sectors. Table B.4 reports also the distribution between short part-time and long-part time for nurses.

<sup>&</sup>lt;sup>8</sup> The PAI register consists of data on workers in public enterprises, including physicians and nurses working in hospitals and health care.

Table B.5 shows the mean of the explanatory variables for married physicians and married registered nurses. Women constitute around 27 per cent of physicians and 95 per cent of nurses. 13 percent of nurses are married with somebody in the health sector and 43 percent of physicians are married with somebody in the health sector. The percentage of nurses with an external job decreases from 7 percent in 1997 to 6 percent in 1999. For physicians, the percentages changes from 10 to 8 percent.

Our model is based on the assumption that we can simulate the different levels of consumption and leisure which could be achieved by each individual in each sector if they chose to work there. Our calculations are based on estimated wage equations done independently for the three years 1997, 1998 and 1999. The resulting levels of possible consumption and leisure are reported in Table B.6 and B.7 respectively. For the states which are observed chosen by an individual, we use observed leisure, while for other potential, but not chosen states, we use average leisure among those observed in the state. Consumption is determined by wage income, capital income, transferincome, and the income of the spouse. All income variables were deflated by the consumer price index. Leisure is expressed as a percentage of available time. Available time includes time over the week-ends and vacation time but excludes 12 hours per day of sleeping and personal care time.

In Appendix C, Tables C.1-C.4, we report the observed transitions across states. Although "stayers" are dominating there are also a considerable amount of "movers".

Appendix D report the data and the estimates of the wage equation.

#### 4. Estimates

In this section we report the results for the labor supply of nurses alongside with the results for physicians estimated by Andreassen et al (2013). We believe that it is useful to make a comparison between nurses and physicians because they are the two most important parts of the health workforce.

Estimation of the utility function is given in Table 1, which also contains the estimation of the

difference between the parameters for nurses and physicians, with the corresponding standard errors and the level of statistical significance.

## (Table 1 approximately here)

The exponents ( $\lambda$  for consumption and  $\gamma$  for leisure) in the utility function are both less than 1 which implies that the utility function is strictly concave. For both medical doctors and nurses, the marginal utility of consumption is declining in consumption. For nurses, the part of the utility that is related to leisure is not significantly different from a log linear function.

The differences between physicians' and nurses' parameters are statistically significant. In particular, the exponent  $\lambda$  for consumption is higher for nurses, while the exponent  $\gamma$  for leisure is higher for physicians implying.

### (Figure 1 approximately here)

The marginal utility of consumption is a concave function of age with a peak around 40 year of age for nurses and 45 for medical doctors, see Figure 1. Therefore the marginal utility of consumption starts declining at a younger age for nurses than for physicians, again indicating that doctors are more concerned about monetary remuneration than nurses.

For both nurses and physicians, the marginal utility of consumption is shifted upwards if the spouse also works in the health sectors. This implies that health workers married to health workers have stronger incentives to work longer hours in the health sector than other health workers.

The impact of having children below the age of 7 on the leisure term is not significantly different from zero for physicians but positive for nurses. Nurses with children below 7 value their leisure time more than physicians with children below 7. Thus nurses with small children are less willing to work long hours compared to physicians. It is interesting to note that the impact of older

children on the marginal utility of leisure is positive and similar for both nurses and physicians

Our result that nurses value leisure more than physicians is re-enforced by the estimate of the parameter of the dummy for females in the leisure term of the utility function. This parameter is not significantly different from zero for physicians but it becomes significant and positive for nurses. The difference in this parameter for nurses and physicians is also statistically significant.

The estimate of the habit persistence parameters,  $\rho$  's, implies that, if age is ignored, the utilities are less correlated across time for doctors than for nurses. Thus physicians are more mobile than nurses. If we take into account age (see Figure 2), the young are more mobile than the old, given wages, taxes and other incentives. As seen in Figure 2 this is particular the case for medical doctors.

#### (Figure 2 approximately here)

Mobility, as captured by the habit persistence parameters, are declining with age, more strongly for physicians than for nurses, and with a weak tendency of increasing again when the health workers are approaching retirement age.

Table 2 provides the estimates of the rationing function, i.e. the availability of jobs. For nurses, the values of the parameters for jobs' availability are higher in absolute values than for physicians, which means that rationing of jobs for nurses is stricter than for physicians. Thus, physicians have more options when it comes to working hours and sectors. For nurses, the estimates also imply that long part time jobs are more available in the public sectors. Full time jobs instead are more available in the private than in the public sector.

#### (Table 2 approximately here)

The goodness of fit for this model is given in Figures 3 and 4. With a few exceptions, in

particular for private hospitals where the observations are few, the model fits the data pretty well.

(Figures 3 and 4 approximately here)

#### 5. Elasticities

In Table 3 we report the impact of an overall wage increase in all years from 1997 to 1999 on labor supply in 1999. In Table 4 we report similar elasticities based on some selected characteristics.

## (Table 3 and 4 approximately here)

We observe that the labor supply of both nurses and doctor are rather inelastic (Table 3). An overall wage increase of 1 percent increases labor supply in terms of total hours of work in 1999 by only 0.03-0.04 percent. However, an overall wage increase is predicted to have a stronger impact on the distribution of physicians and nurses across job types. An overall wage increase is predicted to shift in particular physicians to full time jobs in hospitals. An overall wage increase is predicted to increase the number of nurses working full-time in the private sector.

Table 4 shows the percentage changes in hours in 1999 when wages increase by 1% in all years (1997 to 1999). Labor supply elasticities of physicians do not vary much according to age. However, the wage elasticities of nurses vary more, being higher if they are not working, than if they are working full- time or part-time. The elasticities for those not working are higher for nurses than for physicians. Having young children does not affect the labor supply of physicians (the coefficient is not significantly different from zero), but has a relatively strong effect on the wage elasticities of nurses. These results indicate that for nurses the work/not work decision is more important than for physicians (especially if they have young children), while income plays a greater role for physicians.

#### 6. Policy simulation

In Table 5 we report the impact of change in taxation away from the current progressive tax system towards a flat tax of 28%, which is a substantial change. The change in taxation is implemented for the whole period 1997- 1999. This change in taxation gives the medical doctors an incentive to shift their work from part time jobs to full time jobs, in particular to jobs in the private sector. The reason for this is that wage levels and wage dispersion is much higher in the private than in the public sector. By moving to the private sector and by increasing their working loads, the medical doctor can keep more of their gross gain due to lower taxes. For nurses, the impact of lower taxes is much weaker. Most of them have lower income in potential new jobs, even in the private sector, than physicians, and therefore they do not benefit that much from shifting jobs. Some of the nurses have so low potential income that the flat tax of 28% increases their taxes. Moreover, their spouses get higher disposable income and this also has a negative impact on their labor supply. We therefore find that some quit working.

#### (Table 5 approximately here)

#### 7. Conclusion

We have estimated a discrete choice model with random terms where we allow for these terms to be correlated over time and jobs (habit persistence). Past options and not only the past optimal choices matter for the current choices. Given observed incentives we find that both nurses and in particular medical doctors are mobile when they are young, but there is a weak tendency of higher mobility again when physicians and nurses are approaching retirement age.

Wage increases have a modest impact on labor supply. The overall elasticity for both physicians and nurses are close to zero. These low elasticities shadow to some extent for stronger responses, shifting labor away from part time jobs in the public and private sector towards full time jobs in the private sector when wages are increased. This latter result accords well with facts. In recent years the real wages in Norway have increased substantially and there are now more physicians and nurses working in private hospitals. The regulation of hours is more rigid in the public

than in the private sector.

In our paper, nurses cannot choose any hours that they would like to work, given the job they occupy. They can choose between 10 different sectors with different working loads some in the private sector and some in the public sector, including not working, In order to work more they have to shift job. The availability of the different type of jobs and working loads are estimated in the model, together with preferences. The availability of the different types of jobs capture the institutional constraints in the health sector, determined by employers and unions. These constraint and job persistence in preferences are the main reason for the weak impact of changes in economic incentives on job mobility and labor supply. So, we do not think that a wage change, e.g 10 percent, will move many people from part-time to full-time work. This is our main point and we refer to other papers (like Askildsen, 2003 and Hanel 2014), where institutional constraints and job persistence are ignored. It should also be noted that we use transition data to estimate our model while the above papers use cross-sectional data. Our conclusion is thus that labor supply among nurses is rather inelastic. To increase labor supply in the population of nurses, longer shifts and therefore less part-time work would be more effective. In Norway, the unions have opposed such a change.

Our results indicate that a reform that removes some of the constraints related to the lack of full time jobs for nurses may increase labor supply.

A change in taxation away from the progressive tax system towards a flat tax of 28% gives medical doctors an incentive to shift their job to private hospitals. The reason for this is that the wage level and dispersion is much higher in the private than in the public sector. With a lower and flat tax rate, they can keep more of these private benefits. For nurses the impact is much more modest. Their potential wage when moving is not that much higher than in the public sector, at least compared with the situation for physicians.

## Appendix D. Wage equations and selection effects for nurses, for physicians see Andreassen et al (2013).

We estimate wage equations for all individuals for the three years 1997, 1998 and 1999. The wage equations for physicians are documented in Andreassen et al (2013). The wage equations for nurses are documented below. We take sample selection into account by including the predicted choice probabilities as explanatory variables in the wage equations. These probabilities were the predictions resulting from a simple multinomial logit estimation of sector choice. We show the mean of the explanatory variables used in the estimation of the choice probabilities in Table D.1. The estimates of the choice probabilities are given in Table D.2 and the resulting average predicted probabilities are given in Tables D.3, along with the means of the other variables used in the wage equations. The logit estimations were done on all nurses in a given year, while the wage equations were estimated on all working nurses with observations of wage income. The estimates of the wage equations are given in Table D.5. The wage equations for all nine work sectors have been estimated simultaneously using maximum likelihood, allowing for correlation between the different wages. The parameters  $\sigma_1$  to  $\sigma_9$  are the variance parameters mentioned in the main paper, and the parameters  $\kappa_1$  to  $\kappa_2$  are the parameters allowing for correlation between sectors. As can be seen from the tables these correlation factors are not found to be significant, indicating that there is not much residual correlation between the different wages after correcting for the other explanatory variables. In general being a woman reduces wages, while wages increase with age. Table D.6 shows the mean and predicted hourly wages for nurses and derived from predictions using the estimated wage equations reported above. Table D.7 shows the predicted wages for physicians based on the wage equations documented in Andreassen et. al. (2013). The wages for doctors are higher and vary more than the wages of nurses.

Table D.1. Mean of the explanatory variables for the logit estimation. All nurses.
